Abstract. Ice nucleating particles (INPs) in the atmosphere are responsible for glaciating cloud droplets between 237 and 273 K. Different mechanisms of heterogeneous ice nucleation can compete under mixed-phase cloud conditions. Contact freezing is considered relevant because higher ice nucleation temperatures than for immersion freezing for the same INPs were observed. It has limitations because its efficiency depends on the number of collisions between cloud droplets and INPs. To date, direct comparisons of contact and immersion freezing with the same INP, for similar residence times and concentrations, are lacking. This study compares immersion and contact freezing efficiencies of three different INPs. The contact freezing data were obtained with the ETH CoLLision Ice Nucleation CHamber (CLINCH) using 80 μm diameter droplets, which can interact with INPs for residence times of 2 and 4 s in the chamber. The contact freezing efficiency was calculated by estimating the number of collisions between droplets and particles. Theoretical formulations of collision efficiencies gave too high freezing efficiencies for all investigated INPs, namely AgI particles with 200 nm electrical mobility diameter, 400 and 800 nm diameter Arizona Test Dust (ATD) and kaolinite particles. Comparison of freezing efficiencies by contact and immersion freezing is therefore limited by the accuracy of collision efficiencies. The concentration of particles was 1000 cm^{-3} for ATD and kaolinite and 500, 1000, 2000 and 5000 cm^{-3} for AgI. For concentrations $< 5000 \text{ cm}^{-3}$, the droplets collect only one particle on average during their time in the chamber. For ATD and kaolinite particles, contact freezing efficiencies at 2 s residence time were smaller than at 4 s, which is in disagreement with a collisional contact freezing

process but in accordance with immersion freezing or adhesion freezing. With “adhesion freezing”, we refer to a contact nucleation process that is enhanced compared to immersion freezing due to the position of the INP on the droplet, and we discriminate it from collisional contact freezing, which assumes an enhancement due to the collision of the particle with the droplet. For best comparison with contact freezing results, immersion freezing experiments of the same INPs were performed with the continuous flow diffusion chamber Immersion Mode Cooling chAmber–Zurich Ice Nucleation Chamber (IMCA–ZINC) for a 3 s residence time. In IMCA–ZINC, each INP is activated into a droplet in IMCA and provides its surface for ice nucleation in the ZINC chamber. The comparison of contact and immersion freezing results did not confirm a general enhancement of freezing efficiency for contact compared with immersion freezing experiments. For AgI particles the onset of heterogeneous freezing in CLINCH was even shifted to lower temperatures compared with IMCA–ZINC. For ATD, freezing efficiencies for contact and immersion freezing experiments were similar. For kaolinite particles, contact freezing became detectable at higher temperatures than immersion freezing. Using contact angle information between water and the INP, it is discussed how the position of the INP in or on the droplets may influence its ice nucleation activity.

1 Introduction

Aerosol particles influence the climate system in different ways. They scatter or absorb the incoming solar radiation or can absorb thermal radiation. Aerosol particles also play a role in cloud formation by acting as cloud condensation nuclei (CCN) and as ice nucleating particles (INPs). INPs help ice nucleation depending on their physical and chemical properties, the temperature of the environment and the presence of supercooled droplets. Heterogeneous ice formation may take place with the help of INPs between 237 and 273 K in the mixed-phase cloud regime. In this regime, three pathways of ice nucleation are differentiated, namely, immersion freezing, condensation freezing and contact freezing. In condensation freezing, water vapor condenses on the INP at temperatures < 273 K to form a liquid droplet which freezes instantaneously. Immersion freezing (IF) takes place when an INP acts as CCN and the formed droplet freezes when the temperature is lowered. In contact freezing the INP collides with the droplet followed by freezing. Contact freezing (CF) in the original sense is understood as the process in which freezing of a supercooled droplet results from the collision with an aerosol particle (Ladino Moreno et al., 2013; Vali, 1985). This view of collisional contact freezing has been complemented by Durant and Shaw (2005), who found a higher ice nucleation temperature compared with the immersion mode, when an INP was in contact with the water–air interface of a droplet, from either the inside or the outside (Durant and Shaw, 2005; Gurganus et al., 2014; Fornea et al., 2009; Murray et al., 2012; Shaw et al., 2005). In the following, we refer to a contact nucleation process as adhesion freezing when the position of the INP on the water surface enhances the ice nucleation efficiency compared with immersion freezing and discriminate it from collisional contact freezing, which assumes an enhancement due to the collision of the particle with the droplet.

Various theoretical mechanisms underlying contact freezing have been proposed as explanations for the higher freezing efficiency in contact mode compared with immersion mode. They have been reviewed by Ladino Moreno et al. (2013). Here we discuss them in brief. Cooper (1974) proposed that ice embryos formed on INPs in vapor are able to nucleate supercooled water upon collision with a droplet. His explanation relies on the classical nucleation theory and is based on the prediction that the critical radius of an ice embryo for deposition nucleation is about 4–5 times larger than that for immersion freezing. Therefore, a particle inactive as a deposition nucleus in the vapor, may nevertheless possess ice embryos larger than the critical size for an embryo immersed in water on its surface. Such an embryo may induce freezing when immersed in water. This mechanism was rejected by Fukuta (1975b). Fukuta (1975a) proposed a similar mechanism but with subtle differences. Similar to Cooper (1974), Fukuta (1975a) assumed that subcritical ice clusters form on the particles by vapor deposition. However,

he rejected that these clusters remain active, once they are immersed in the droplet as proposed by Cooper (1974). Instead, he assumed that freezing occurs during the wetting process when the water front moves over the particle because this process gives rise to a transient high free-energy zone which facilitates nucleation. This process should be only valid for hydrophobic nuclei. While the older theories focus on a collisional contact freezing mechanism, the more recent ones concentrate on adhesion freezing. Indeed, experimental studies by Shaw et al. (2005) and Fornea et al. (2009) have shown that an INP that is not completely immersed in the droplet can trigger ice nucleation at higher temperatures. From simulations, Sear (2007) found that the nucleation rate is 4 orders of magnitude higher along the contact line where the water surface meets the surface of the particle. Based on classical nucleation theory, he considered this result as generic. Suzuki et al. (2007) found from their experiments with water droplets on silicon surfaces coated with various silanes that the temperature at which nucleation occurs at a contact line depends on the contact angle between water and the substrate. On the other hand, Gurganus et al. (2011, 2013) investigated the freezing of droplets deposited on clean and coated silicon wafers and did not observe any preference of nucleation at the contact line. The same group also studied this phenomenon on catalyst substrates with imposed surface structures and found that the preferred nucleation site was the contact line in the case of nanoscale texture but not for microscale texture (Gurganus et al., 2014). Djikaev and Ruckenstein (2008) proposed that the line tension associated with the three phase contact line may indeed play an important role. On the other hand, Niehaus and Cantrell (2015) investigated soluble INPs for contact freezing. They showed that ionic salts can trigger freezing of moderately supercooled water. They concluded that this freezing effect must depend on collision between the water droplet and INP since the particles they used dissolve when they become immersed in water.

Ladino Moreno et al. (2013) reviewed experimental studies on contact freezing and also pointed out large discrepancies in the available experimental data. Quantification of the number of INPs required for contact freezing, the time dependence of contact freezing, and dependence on particle type and size were listed amongst the most uncertain parameters. Hoffmann et al. (2013a, b) and Niehaus et al. (2014) attempted to quantify the number of INPs required to freeze a droplet by contact freezing for their respective experiments. In Hoffmann et al. (2013a, b), a highly electrified droplet is suspended in an electrodynamic balance. The freezing probability of a droplet on a single collision was shown to be a steep function of temperature. Nine collisions were necessary to freeze the droplet at 244 K, while a single collision was sufficient to freeze the droplet at 239 K for illite particles with a mobility diameter of 750 nm. They conclude that contact freezing is the dominant mechanism over immersion freezing (Hoffmann et al., 2013a). Niehaus

et al. (2014) found that for mineral dust from different origins, 10^3 to 10^5 particles had to collide with a droplet deposited on the glass slide in the temperature range of 253 to 258 K. Moreover, they ran experiments in which they melted a droplet after having observed a freezing event. When they cooled it back to the original temperature, no freezing event occurred. From this, they concluded that contact freezing was more probable than immersion freezing and that the particle–droplet collision was responsible for freezing. Contact freezing and immersion freezing have been previously compared by Levin and Yankofsky (1983) for bacterial cells where onset temperatures for contact freezing were shown to be 2 K higher. However, they did not state how many particles were needed to collide with the droplets to initiate freezing. Ladino et al. (2011) concluded that there are some hints that contact freezing is more efficient than immersion freezing for kaolinite particles. They attempted to derive the freezing efficiency per single particle using theoretical formulations of collision efficiencies to calculate the number of collisions between droplets and particles and obtained unrealistic freezing efficiencies on the order of 10 to 100 for 26 μm diameter droplets and 400 nm kaolinite particles. The too large values of the freezing efficiency were attributed to the overestimation of droplet size in calculating collision efficiency. They also mistook liquid droplets for frozen droplets because multiple droplets were simultaneously present in the laser beam of the detector (Ladino Moreno et al., 2013).

The relevance of contact freezing for the atmosphere depends on the collision rate and the freezing efficiency. The collision rate between particles and droplets is a function of the collision efficiency, which is not well determined in the accumulation mode size range as pointed out by Nagare et al. (2015). Collision efficiency (CE) is defined as the fraction of particles in the cylindrical volume swept out by a falling droplet that collides with it. CE depends mainly on particle size and droplet size. Other factors which influence CE are the relative humidity of the environment and charges on droplets and particles. For Aitken mode particles, Brownian motion of the particles is usually the dominant collision process and CE can exceed 1 because of the high mobility of the particles in this size range. For coarse-mode particles, impaction and interception of particles are the dominant contributors to CE. The minimum of CE (Greenfield gap) is in the accumulation mode where thermophoresis and diffusio-phoresis may also contribute to CE (Nagare et al., 2015).

In order to compare the efficiency of immersion freezing and contact freezing, we performed a series of experiments with silver iodide, kaolinite and Arizona Test Dust (ATD) in immersion and contact freezing mode. Silver iodide is known to be a very good ice nucleus (Vonnegut, 1949) inducing ice nucleation up to 269 K, while ATD and kaolinite become efficient ice nuclei only at lower temperatures. Silver iodide has been reported to nucleate ice more efficiently in contact than in immersion mode (DeMott, 1995). Kaolinite and ATD have been widely tested in laboratory studies as immersion

freezing nuclei. Kaolinite is a clay mineral and accounts for 13 % of dust mass in the atmosphere (Atkinson et al., 2013). It has been studied previously in immersion freezing (e.g., Welti et al., 2012) and contact freezing studies (e.g., Ladino et al., 2011; Svensson et al., 2009). ATD has been previously studied for immersion freezing by Marcolli et al. (2007) and Niedermeier et al. (2010) and for contact freezing by Niehaus et al. (2014). ATD is composed of quartz, feldspar, carbonate, illite, kaolinite and other clays (Broadley et al., 2012).

2 Experimental setups and procedures

2.1 Instrument description

2.1.1 CLINCH setup

Contact freezing data were obtained with the ETH CoLLision Ice Nucleation CHamber (CLINCH). This instrument has been used previously by Ladino et al. (2011) for a contact freezing study with kaolinite particles as INPs. In CLINCH, aerosol and water droplets collide and may freeze by contact. The extension of the chamber length from 40 cm, as used by Ladino et al. (2011), to 80 cm for the current study makes it possible to observe the frozen fraction of droplets (FF), i.e., the ratio of the number of frozen droplets to the total number of droplets, at residence times of 2 and 4 s with 80 μm diameter droplets compared to 26 μm droplets used by Ladino et al. (2011). The droplet diameter is changed from 26 to 80 μm in order to increase the geometrical volume swept out by the droplet and to avoid a significant change in the droplet size due to evaporation in the chamber. Droplets with diameters of $80 \pm 3 \mu\text{m}$ are generated with a droplet generator (Ulmke et al., 2001) at the top center of the chamber with a frequency of 100 Hz. The droplets are generated with pure water (Milli-Q, 18.2 M Ω) at a temperature of 281 K. The relaxation time for a droplet to reach its terminal velocity (0.186 ms^{-1}) is 0.2 s, and the time needed to reach the target temperature is about 0.1 and 0.6 s when the chamber is kept at 261 and 235 K, respectively (Nagare et al., 2015). While performing the experiment, the walls of the chamber are coated with a thin layer of ice creating an ice-saturated environment inside the chamber.

Aerosol particles enter the chamber at the top in air streams from both sides with a flow velocity of 1 L min^{-1} and can interact with the droplets inside the chamber. FF can be determined with the Ice Optical DEtector (IODE) developed in-house (Nicolet et al., 2010; Lüönd et al., 2010), which discriminates water droplets from ice crystals by measuring the depolarization of the backscattered light of a laser beam. In order to avoid the presence of several droplets simultaneously in the laser beam, a new laser was installed (402 nm, Schaefer + Kirchhoff laser Makroliniengenerator13LTM) providing a rectangular instead of a circular laser beam. At each temperature, a blank experiment without aerosol parti-

cles was performed before the aerosol stream was turned on. A more detailed description of the instrument and experiment is given in Nagare et al. (2015).

2.1.2 IMCA–ZINC setup

Immersion freezing experiments were performed using the IMCA–ZINC setup (Welti et al., 2012). This setup combines the Zurich Ice Nucleation Chamber (ZINC) (Stetzer et al., 2008) with the vertical extension Immersion Mode Cooling chamber (IMCA) (Lüönd et al., 2010). In brief, the aerosol particles are activated as CCN in the IMCA part at a relative humidity with respect to water $> 120\%$ and temperature $> 300\text{ K}$. These activated droplets are then cooled down in the IMCA part and reach the target temperature for freezing when they enter the ZINC chamber. The droplets are $18\text{--}20\ \mu\text{m}$ in diameter when they leave the IMCA part and enter the water-saturated environment in ZINC which is created by ice coatings on the parallel walls, which are kept at different temperatures. FF can be determined using the depolarization detector IODE at different residence times from 1 to 21 s. A more detailed description of the instrument and experiment is given in Welti et al. (2012). Characteristics of the IMCA–ZINC and the CLINCH experiments are compared in Table 1.

2.2 Aerosol generation and sampling

Silver iodide was precipitated by mixing 0.1 M solutions of potassium iodide and silver nitrate. The aerosol particles were generated by atomizing this suspension and dried (for details, refer to Nagare et al., 2015). The suspension was usually prepared the day before a measurement series was started and used for a measurement series performed during, typically, 2 days. Between measurements the suspension was kept in the dark. Kaolinite (Fluka, Sigma Aldrich GmbH) and ATD (Powder Technology Inc.) particles were aerosolized in a fluidized bed aerosol generator (TSI Model 43400A). The aerosol stream was passed through a cyclone to remove large particles. Aerosol particles were selected based on their electrical mobility with a differential mobility analyzer (DMA TSI 3081) with an upstream impactor. These size selected particles were used for either contact or immersion freezing experiments in the respective experimental setups. The concentration of particles in CLINCH was measured at the end of the chamber using a condensation particle counter (CPC, TSI 3772).

2.3 Particle sprinkling experiment

We sprinkled polydisperse particles of AgI, ATD and kaolinite gently on a water surface to observe optically whether they adhere to the surface or sink to the bottom. The particles were sprinkled on Milli-Q water at room temperature by gently shaking a spatula loaded with a small portion of the powders.

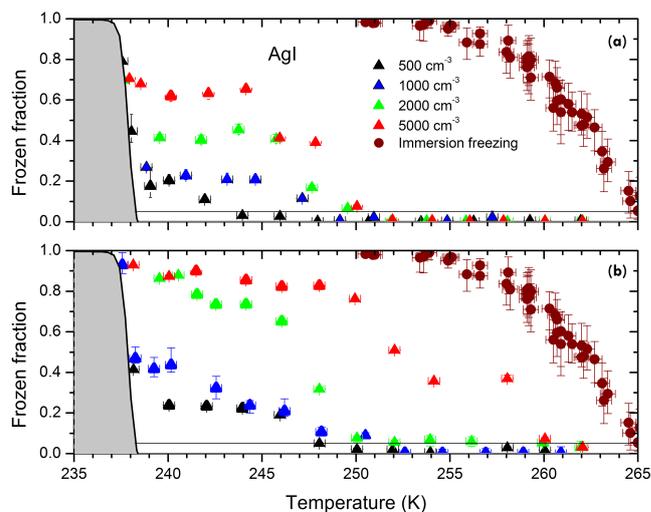

Figure 1. Frozen fraction against chamber temperature for silver iodide particles of 200 nm diameter. Contact freezing for aerosol concentrations from 500 to 5000 cm^{-3} is given by triangles for a droplet residence time of 2 s in panel (a) and 4 s in panel (b). Immersion freezing for a 3 s residence time of droplets in the ZINC chamber is shown by circles. The gray shaded area shows the homogeneous freezing of droplets determined from blank experiments (without aerosol) and the black horizontal line indicates the lower reliability limit of the measurements determined from the blank signal level observed in experiments without aerosol. Error bars represent the uncertainty in the frozen fraction due to the classification (liquid or ice) uncertainty of the IODE detector (Lüönd et al., 2010).

3 Experimental results

Figure 1 shows the FF observed for silver iodide as INP in CLINCH (triangles) as a function of chamber temperatures for droplet residence times of 2 s in panel (a) and 4 s in panel (b) for different concentrations of silver iodide. The gray shaded area is the experimentally determined homogeneous freezing regime of droplets in CLINCH from blank experiments. The black horizontal line marks the lower reliability limit of differentiation between ice and water determined from blank experiments. As the temperature of the chamber decreases to $< 250\text{ K}$, the FF starts to rise and then remains constant. The frozen fraction due to immersion freezing from IMCA–ZINC experiments with a 3 s residence time in the ZINC chamber is shown as circles for comparison with contact freezing. Silver iodide particles produced by our method are found to be much more efficient INPs in terms of onset temperature in immersion than in contact freezing mode. The onset temperature for silver iodide particles is 265 K , while for contact freezing significant frozen fractions were observed only below 250 K except for the highest concentration and 4 s residence time. For the highest concentration used in our experiment, the onset temperature for contact freezing is 258 K .

Table 1. Instrument characteristics

Instrument	Droplet diameter (μm)	Residence time of droplet (s)	Aerosol concentration
IMCA–ZINC	18–20	3 (variable)	1 particle per droplet
CLINCH	80 ± 3	2 and 4	$500\text{--}5000\text{ cm}^{-3}$ air

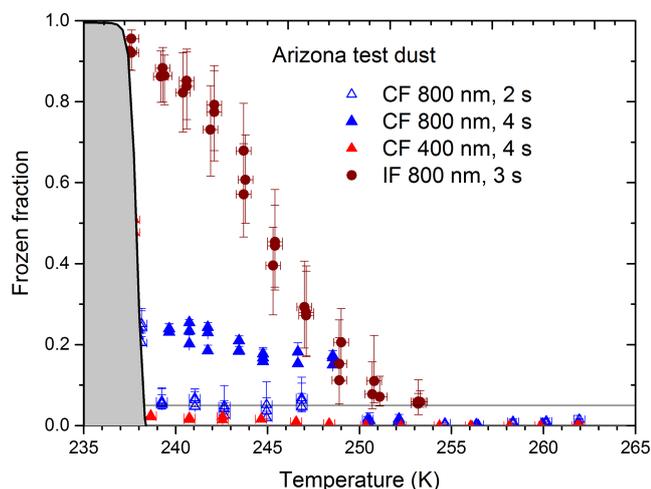

Figure 2. Frozen fraction against chamber temperature for ATD particles of 400 nm and 800 nm diameter. Contact freezing (CF) for aerosol concentrations of 1000 cm^{-3} is given by triangles for droplet residence times of 2 and 4 s. Immersion freezing (IF from IMCA–ZINC) for 800 nm ATD particles and a 3 s residence time in ZINC is shown by circles. The gray shaded area shows the homogeneous freezing of droplets determined from blank experiments (without aerosol), and the black horizontal line indicates the lower reliability limit of the measurements determined from the blank signal level observed in experiments without aerosol. Error bars represent the uncertainty in the frozen fraction due to the classification (liquid or ice) uncertainty of the IODE detector (Lüönd et al., 2010).

Figure 2 shows the frozen fraction of droplets when ATD particles were used as INPs in contact and immersion freezing mode. The frozen fraction due to immersion freezing is shown for 800 nm particles and a 3 s residence time in the ZINC chamber. There is no significant difference in onset temperature for immersion and contact freezing for ATD. Figure 3 shows the frozen fraction for experiments performed with kaolinite. For these INPs, the onset temperature of contact freezing is 3 K higher than for immersion freezing. Possible reasons for this will be discussed in Sects. 5.2.3 and 5.2.4.

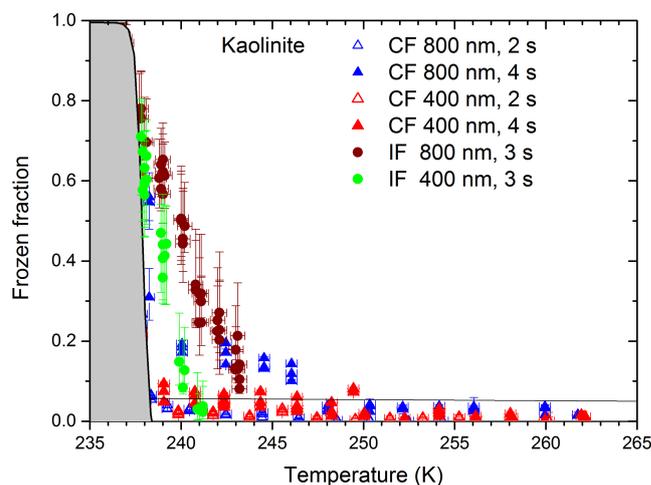

Figure 3. Frozen fraction against chamber temperature for kaolinite particles of 400 and 800 nm diameter. Contact freezing (CF) for aerosol concentrations of 1000 cm^{-3} is given by triangles for droplet residence times of 2 and 4 s. Immersion freezing (IF from IMCA–ZINC) for 400 and 800 nm kaolinite particles and a 3 s residence time in ZINC is shown by green and brown circles, respectively. The gray shaded area shows the homogeneous freezing of droplets determined from blank experiments (without aerosol), and the black horizontal line indicates the lower reliability limit of the measurements determined from the blank signal level observed in experiments without aerosol. Error bars represent the uncertainty in the frozen fraction due to the classification (liquid or ice) uncertainty of the IODE detector (Lüönd et al., 2010).

4 Freezing efficiencies

4.1 Calculation of freezing efficiency from frozen fraction

The frozen fraction measured by CLINCH depends on the collision efficiency and the freezing efficiency (FE). For a further evaluation and comparison of contact freezing and immersion freezing FF has to be converted to FE. If a droplet freezes after more than one particle has hit it, it is not clear which particle induced freezing. Assuming that all collisions were needed for freezing leads to the following equation:

$$\text{FE} = \frac{\text{FF}}{N}, \quad (1)$$

where N is the number of collisions for a droplet with the aerosol particles and can be calculated as (Ladino et al.,

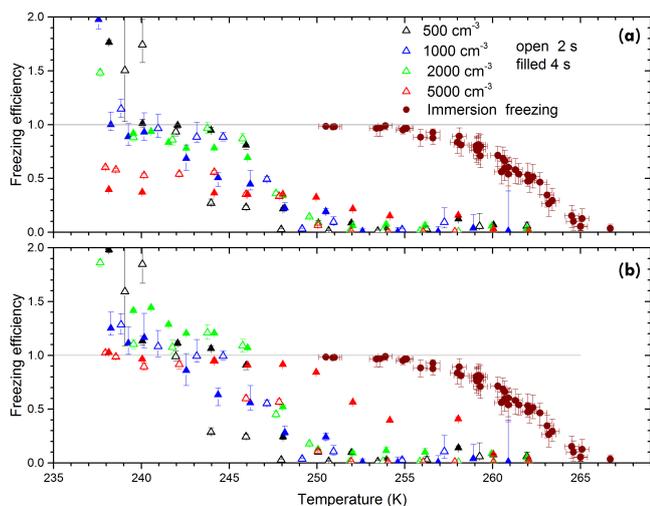

Figure 4. Freezing efficiency FE against chamber temperature for contact freezing experiments (triangles) with 200 nm diameter AgI particles with droplet residence times of 2 s (open symbols) and 4 s (filled symbols). The concentration of silver iodide particles varies from 500 to 5000 cm⁻³. A collision efficiency CE = 0.13 is used to calculate N . FE is calculated using Eq. (1) in panel (a) and Eq. (4) in panel (b). Immersion freezing of droplets in the ZINC chamber for a 3 s residence time is shown as circles. The gray horizontal line indicates the maximum freezing efficiency realized when the first collision initiates freezing.

2011)

$$N = CE \times C \times L \times \pi \times (R + r)^2, \quad (2)$$

where C is the concentration of the particles, R and r are the radii of droplets and particles, respectively, and L is the effective length experienced by the droplet given as

$$L = \frac{U(R)l}{U(R) + V_{\text{flow}}}, \quad (3)$$

where l is the geometrical length traced by the droplet, $U(R)$ is the terminal velocity of the droplet and V_{flow} is the flow velocity of the carrier gas in CLINCH.

Equation (1) assumes that the droplet has collected N particles and freezes due to the last particle that it has collected. However, the droplet can freeze on collision with the first particle and then collect other particles. Assuming that one collision is enough for ice nucleation, leads to the following expression for FE:

$$FE = \frac{FF}{1 - e^{-N}}. \quad (4)$$

Here the denominator indicates the fraction of unfrozen droplets after N collisions with the particles. We use this formula in the case of AgI because we expect for this ice nucleus FE = 1 at $T < 245$ K (Nagare et al., 2015). While Eq. (1) gives a lower limit of FE, Eq. (4) gives the upper limit.

Since FE is derived by normalizing FF with respect to N , FE should be independent of the residence time when the number of collisions is < 1 . If freezing efficiencies of 2 s (FE(2 s)) and 4 s residence times (FE(4 s)) are the same within the experimental uncertainty, this can be considered as an indication of immediate freezing when the first particle collides with a droplet. Conversely, FE(4 s) $>$ FE(2 s) suggests that freezing is not immediate when a particle hits a droplet but that more time is needed on average. Such a time-dependent freezing process would be in accordance with an immersion freezing mechanism assuming that the droplet only freezes when the particle becomes immersed. A time dependence is also expected for adhesion freezing when the particle adheres to the surface of the droplet. If $N < 1$, it is unlikely that FE is influenced by the number of collisions and we will interpret FE(2 s) = FE(4 s) as a criterion for collisional contact freezing and FE(4 s) $>$ FE(2 s) as a criterion for freezing in immersion mode or adhesion freezing.

4.2 Freezing efficiency of silver iodide particles

We derived a collision efficiency CE = 0.13 for 200 nm diameter AgI particles with 80 μm droplets in our previous study (Nagare et al., 2015). This number is an order of magnitude higher than the values calculated with commonly used theoretical formulations of collision efficiencies. Figure 4 shows FE of 200 nm diameter silver iodide particles for droplet residence times of 2 s (open symbols) and 4 s (filled symbols) calculated using Eqs. (1) (panel a) and (4) (panel b). The number of collisions for the different particle concentrations range between 0.11 and 2.35 as listed in Table 3. Panel (a) of Fig. 4 shows that FE does not exceed 0.5 for $C = 5000$ cm⁻³ for 4 s residence time. For this concentration and residence time 2.35 collisions occurred in the chamber and freezing may have been induced by any of these collisions. Equation (1) assumes that indeed all collisions are necessary to freeze a droplet and gives a lower limit of freezing efficiency. An upper limit is obtained using Eq. (4), which assumes that the first collision induces freezing. Panel (b) of Fig. 4 shows that this assumption leads to a grouping of FE data around 1 for $T < 245$ K for all particle concentrations and residence times of 2 and 4 s. This reinforces the assumption that the first contact leads to droplet freezing in this temperature range and confirms the plateau condition used in Nagare et al. (2015) to derive CE. We ascribe data points with FE $>$ 1 to homogeneous freezing and measurement uncertainties. For $T > 252$ K, FE values significantly different from zero are only reached for concentrations of 5000 cm⁻³. This would imply that above this temperature more than one collision is necessary for droplet freezing in CLINCH. For $T < 245$ K, FEs for 2 and 4 s residence times are the same within measurement uncertainties suggesting that ice nucleation occurs immediately when the particle hits the droplet. At higher temperatures the data points are quite scattered impeding a clear conclusion. Also shown are immersion freez-

Table 2. Average number of collisions for 800 nm particles with a 80 μm diameter droplet in a concentration of 1000 cm^{-3} and residence times of 2 and 4 s assuming different values for CE.

Collision efficiency CE	Number of collisions N	
	2 s	4 s
0.0033	0.0056	0.012
0.046	0.079	0.168
0.13	0.24	0.48

ing measurements with IMCA–ZINC with AgI particles that were prepared the same way as the ones for the contact freezing experiments. Residence time in the ZINC chamber was 3 s. Surprisingly, the onset temperature and the efficiency for immersion freezing are significantly higher than for contact freezing. This observation is further discussed in Sect. 5.2.1.

4.3 Freezing efficiency of ATD particles

Figure 5 shows FE in contact freezing mode for 800 nm ATD particles calculated using Eq. (1). N is calculated based on four different assumptions for CE. For panel (a), $\text{CE} = 0.0033$ from the theoretical formulation by Park et al. (2005) and Wang et al. (1978) was used. Details of the calculations are given in Nagare et al. (2015), where discrepancies between theoretical calculations and experimental observations have been addressed. For 200 nm silver iodide particles, the experimentally determined CE is 14 times higher than the calculated one. In order to adjust FE better to the theoretical upper limit of $\text{FE} = 1$ and due to a lack of other available experimental values, the calculated collision efficiency was multiplied by a factor of 14 to calculate N for panel (b). For a lower limit, the experimentally derived CE for 200 nm AgI particles ($\text{CE} = 0.13$) was used to calculate N in panel (c). In panel (d), $\text{CE} = 0.061$ was used, which shifts FE of 800 nm ATD particles close to 1, which is in accordance with the assumption that each collision leads to droplet freezing. The calculated CE shown in panel (a) leads to unrealistically high FE. This was also observed by Ladino et al. (2011). Using a correction factor of 14 for CE still yields FE values > 1 . Panels (c) and (d) give best estimates of lower and upper limits of freezing efficiency. The difference in FE between panels (c) and (d) must be considered as an uncertainty due to the lack of reliable theoretical values of CE in the investigated temperature and particle size range. The number of collisions for the different assumptions of CE is listed in Table 2. For the lower-limit case with $\text{CE} = 0.13$, FE reaches values up to 0.5 for data points that can be unambiguously assigned to heterogeneous freezing. Contact freezing experiments do not show significantly different onset temperatures compared with immersion freezing experiments carried out with the IMCA–ZINC setup, where every droplet contains one particle. The active site parameterization developed by Marcolli et al. (2007) based on DSC (differential scanning

Table 3. Average number of collisions N for 200 nm silver iodide particles with a 80 μm diameter droplet in concentrations from 500 to 5000 cm^{-3} air and residence times of 2 and 4 s.

Concentration (cm^{-3})	2 s	4 s
500	0.11	0.23
1000	0.23	0.47
2000	0.47	0.94
5000	1.17	2.35

calorimeter) experiments is shown as a brown line in Fig. 5. It agrees well with the immersion freezing experiments carried out with 800 nm particles in the IMCA–ZINC chamber. Taking $\text{CE} = 0.061$ (panel d), contact freezing may be slightly more efficient than immersion freezing. Taking $\text{CE} = 0.13$ (panel c), contact freezing and immersion freezing seem to be similarly efficient. We did not convert the frozen fraction of 400 nm ATD particles to freezing efficiency because FF is close to the detection limit. For all assumed values of collision efficiencies, the freezing efficiency at a 4 s residence time is almost twice the value at a 2 s residence time. As listed in Table 2 the number of collisions is < 1 for both residence times. While the uncertainty associated with the measurements at 2 s is quite large, this data still seems significantly lower than the 4 s residence time freezing efficiencies. An increasing freezing efficiency with increasing residence time is expected for immersion freezing (Hoffmann et al., 2013b; Welti et al., 2012) and adhesion freezing. Therefore, it is likely that freezing occurs due to one of these mechanisms rather than collisional contact freezing.

4.4 Freezing efficiency of kaolinite particles

Figure 6 shows the freezing efficiency of 800 nm diameter kaolinite particles for 2 s (open triangles) and 4 s (filled triangles) residence times. The frozen fraction measured for 400 nm particles was not significant; therefore, we do not convert these data to freezing efficiency. Panels (a), (b) and (c) use three different assumptions to calculate N , as explained in the previous section for ATD. For panel (a) the theoretical formulations were used, while panels (b) and (c) give the upper and lower limit of FE, respectively. Shown as brown circles in Fig. 6 are the immersion freezing results of 800 nm Fluka kaolinite particles for a 3 s residence time in the ZINC chamber. Freezing efficiencies are in good agreement with the previously published α -pdf parameterization by Welti et al. (2012) derived from immersion freezing experiments performed with the same setup (brown line). In Wex et al. (2014) immersion freezing experiments with 700 nm kaolinite (Fluka) particles were performed with LACIS (Leipziger Aerosol and Cloud Interaction Simulator; shown as blue diamonds) and with a CFDC (Continuous Flow Diffusion Chamber; shown as green diamonds). In the LACIS instrument, INPs are activated to droplets at

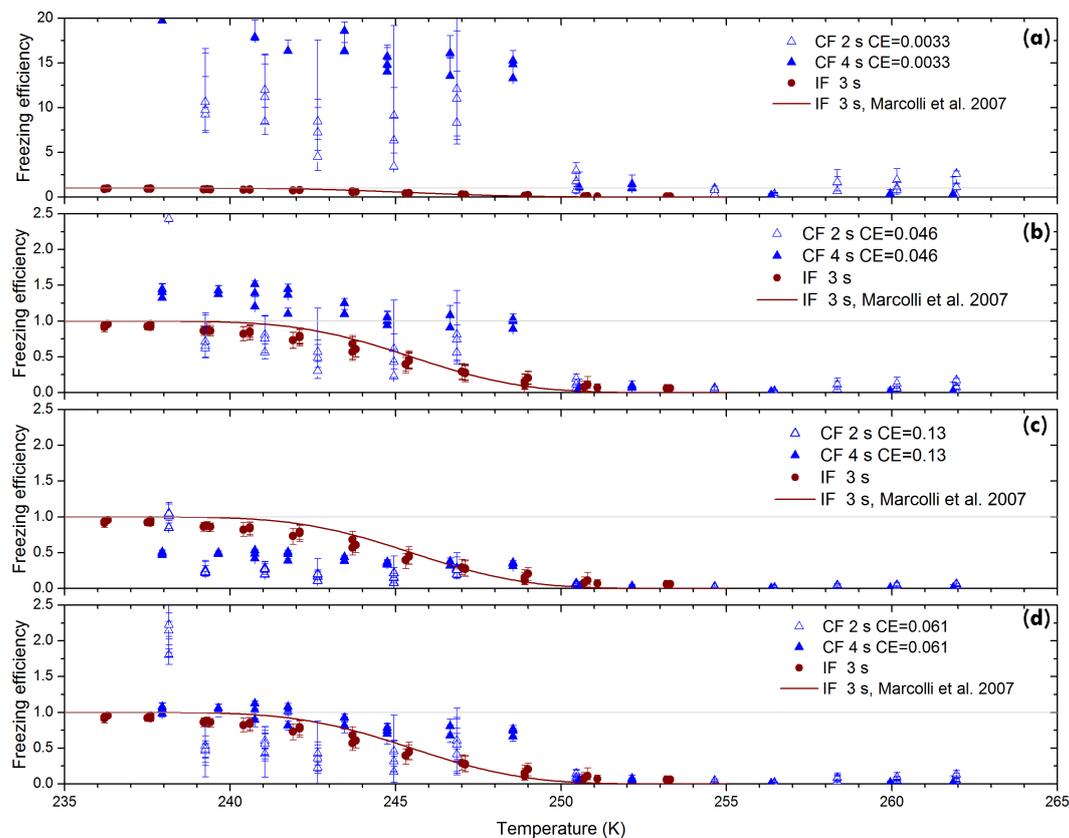

Figure 5. Freezing efficiency for 800 nm ATD particles with a concentration of 1000 cm^{-3} calculated with four different assumptions for CE: panel (a), with theoretical CE from Wang et al. (1978) and Park et al. (2005); panel (b), with $14\times$ CE from panel (a) (see text for details); panel (c), with CE = 0.13 (applying the value for 200 nm AgI particles for all particle sizes); panel (d), with CE = 0.061, which shifts collision efficiencies close to 1. Filled triangles show contact freezing for 4 s residence time in the CLINCH chamber; the open triangles are for 2 s residence time. Each triangle represents an independent measurement. Error bars represent the precision of the IODE detector. Brown circles show the freezing efficiency for immersion freezing of droplets in the IMCA–ZINC chamber for a 3 s residence time. The brown lines show the FF calculated with the active site immersion freezing parameterization from Marcolli et al. (2007) evaluated for 800 nm particles and a 3 s residence time. The gray horizontal line indicates FE = 1. Note that the y scale in panel (a) is different from the ones in panels (b), (c) and (d).

$T = 257\text{--}260\text{ K}$ while cooling to the targeted temperature. They are at the experimental temperature during 1.6 s while they evaporate. This lower residence time may explain the lower freezing efficiency observed in LACIS compared with IMCA–ZINC. Slightly higher freezing efficiencies than in LACIS but still lower than in IMCA–ZINC were observed for 700 nm Fluka kaolinite particles in the CFDC (orange stars: Tobo et al., 2012; green diamonds: Wex et al., 2014). The contact freezing efficiencies from CLINCH are clearly higher for the lower limit of CE = 0.046 and slightly higher for the upper limit of CE = 0.13.

5 Discussion

5.1 Collision efficiency

Collision efficiency is a crucial parameter for an accurate comparison of contact and immersion freezing. Figures 5 and 6 show that freezing efficiencies of ATD and kaolinite particles calculated with theoretical formulations of CE are at least 1 order of magnitude too high. This corroborates the finding by Nagare et al. (2015) that CE formulations need to be reassessed for temperature below 273 K. More such studies for different particle and droplet sizes are needed to improve the database for the validation of calculated collision efficiencies at subzero temperatures, subsaturation with respect to water, and droplets and particles with known charges. For measurements with the AgI aerosol, FE = 1 could be assumed for data points at $T < 245\text{ K}$ because they showed constant frozen fractions and IMCA–

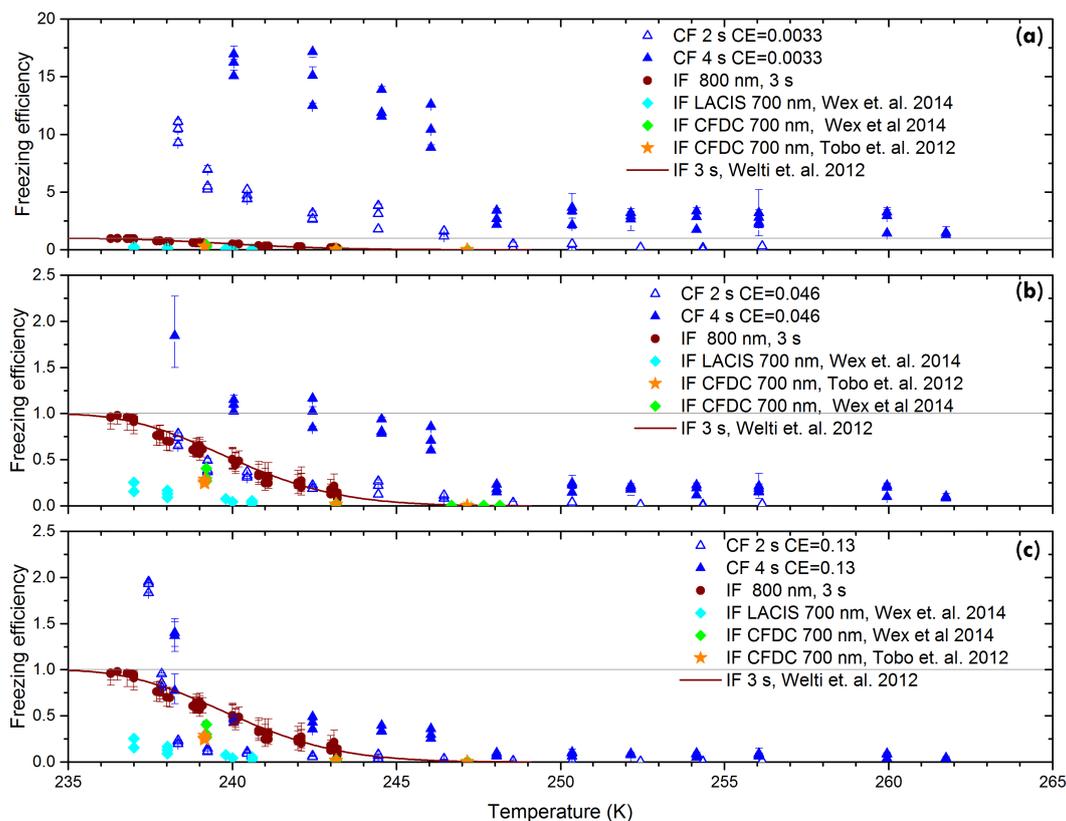

Figure 6. Freezing efficiency for 800 nm kaolinite particles with a concentration of 1000 cm^{-3} calculated with 3 different assumptions for CE: panel (a), with the theoretical CE from Park et al. (2005) and Wang et al. (1978); panel (b), with $14\times$ CE from panel (a); panel (c), with $\text{CE} = 0.13$ (applying the value of 200 nm AgI particles) for lower bound of freezing efficiency. Each triangle represents an independent measurement. Error bars represent the precision of the IODE detector. Brown circles show the freezing efficiency of droplets in ZINC for a residence time of 3 s for 800 nm kaolinite particles. Orange stars show immersion freezing of droplets activated by 700 nm Fluka kaolinite particles (from Fig. 2a of Tobo et al., 2012). Light blue diamonds show immersion freezing of droplets activated by a 700 nm Fluka kaolinite particle (LACIS data with 1.6 s residence time (from Fig. 2 (right panel) of Wex et al., 2014)). The green diamond shows immersion freezing of droplets activated by 700 nm kaolinite particles (CFDC data with 5 s residence time (from Fig. 2 (right panel) of Wex et al., 2014)). The brown line represents the α -pdf parameterization from Welts et al. (2012). The gray horizontal line indicates the maximum freezing efficiency. Note that the y scale for panel (a) is different from the ones in panels (b) and (c).

ZINC experiments determined $\text{FE} = 1$ at $T < 245\text{ K}$. For ATD and kaolinite, there was no temperature range where freezing occurred with an efficiency of 1. Therefore, only upper and lower limits of collision efficiency can be estimated. This limits the comparison of contact with immersion freezing. Collision efficiency is also a crucial factor for quantifying the lifetime of the accumulation mode aerosol in the atmosphere because their lifetime strongly depends on the scavenging rate of particles by the droplets (Seinfeld and Pandis, 2006).

5.2 Contact freezing process

The higher FEs for 4 s than for 2 s residence time in the CLINCH experiments with ATD and kaolinite are in agreement with adhesion freezing and immersion freezing. This indicates that collision itself does not increase FE, but there

seems to be an effect depending on whether the INP adheres to the water surface or is immersed in the droplet. The situation is less clear for AgI. For contact freezing experiments FE at 2 s is the same as for 4 s residence time within error when on average one AgI particle or less collides with the droplet in the chamber. This result is in agreement with a collisional contact freezing mechanism but may also result from a very high nucleation rate of immersion freezing and/or adhesion freezing at the investigated temperature.

When a particle adheres to the surface, it may induce ice nucleation in contact mode by the part exposed to air and immersion freezing by the part immersed in water. When an insoluble or slightly soluble particle acts as cloud condensation nucleus (CCN), it is usually assumed that it becomes totally immersed in the droplet. However, whether the particle adheres to the droplet surface or becomes totally immersed depends on the wetting behavior of the particle (see

Appendix A). The consequences for ice nucleation are discussed below for the investigated INPs.

5.2.1 Silver iodide

For AgI particles, freezing efficiencies for 2 and 4 s residence times are the same within experimental uncertainties, which is in accordance with immediate freezing after collision. However, adhesion freezing and immersion freezing cannot be excluded if these processes occur at a high rate. Whether AgI adheres to the surface after collision or becomes totally immersed depends on the contact angle between water and the AgI surface. Billett et al. (1976) observed a dependence of the contact angle on the silver ion concentration in the solution. For silver iodide prepared in a stoichiometric ratio, they determined $\alpha = 45\text{--}50^\circ$ for the intermediate advancing angle. We observed that most of the AgI particles adhered to the surface when we sprinkled them gently on water. This is in accordance with observations by Gokhale and Goold (1968) and Gokhale and Lewinter (1971). We therefore assume that silver iodide particles remain on the droplet surface after collision in the CLINCH chamber. It is also likely that the AgI particles adhere to the droplet surface in the ZINC chamber after activation in the IMCA chamber. Therefore, in the CLINCH and IMCA–ZINC experiments, the efficiency of adhesion freezing is probed, and it could be expected that freezing efficiencies in both experiments are the same. However, the IMCA–ZINC freezing experiments performed with the same AgI aerosol and similar residence times show a much higher freezing efficiency than the CLINCH experiments. This is in contrast to DeMott (1995), who reported higher freezing efficiencies in contact than in immersion mode for AgI–AgCl aerosols. However, AgI is a complex ice nucleus that appears in different polymorphic forms. Moreover, it partly dissolves in water. Depending on the production procedure, AgI is agglomerated with soluble salts. Moreover, the freezing ability depends on the surface charge of AgI particles. A closer investigation of factors influencing the efficiency of AgI as an ice nucleus and reasons for the lower freezing efficiency in CLINCH compared with IMCA–ZINC are discussed in the companion paper by Marcolli et al. (2016).

5.2.2 Arizona Test Dust

The ice nucleation ability of ATD has been investigated by several groups using different setups. Niehaus et al. (2014) investigated contact freezing of deposited droplets on a glass slide; the droplets were exposed to a flow of a polydisperse ATD aerosol (0.3–10 μm diameter particles). They determined that 1 in 1000 particles induced freezing at 253 K, and 1 in 100 000 did so at 258 K. These numbers are not directly comparable with this study because the detection limit for frozen fractions of the IODE detector is ca. 0.05. In CLINCH we observed the onset of freezing at 247 K for 800 nm ATD

particles. For 800 nm ATD particles, the freezing efficiencies in contact mode are, within experimental uncertainties, the same as freezing efficiencies in immersion mode measured with IMCA–ZINC at a 3 s residence time. When the ATD parameterization for immersion freezing proposed by Marcolli et al. (2007) is applied to 800 nm particles with a nucleation time of 3 s, it agrees well with the experimental data from IMCA–ZINC. Niedermeier et al. (2010) investigated immersion freezing of ATD particles with LACIS. Experiments with ATD aerosols with diameters < 560 nm yielded frozen fractions of 0.04 at 239 K and 0.1 at 236 K. The low residence time and the cutoff of particles > 560 nm may be reasons for this lower freezing efficiency compared with IMCA–ZINC. When the active site parameterization by Marcolli et al. (2007) is applied to 400 nm particles, it gives too high active fractions compared to experiments. The heterogeneous mineralogical composition of ATD may be one of the reasons that smaller particles do not act as effective INPs and may even be inactive. Atkinson et al. (2013) have shown that ATD is composed of 20.3 % K-feldspar, 12.4 % (Na, Ca)-feldspar, 17.1 % quartz, 7.5 % illite/muscovite and 10 % illite/smectite. Clay mineral particles of illite/muscovite tend to be small and presumably dominate the particle fraction with diameters < 500 nm, while quartz and K-feldspar may be overrepresented in the fraction with diameters > 500 nm. Moreover, larger particles are often conglomerates of different minerals (Reid et al., 2003; Kandler et al., 2011) and may contain contributions of some K-feldspar, while small particles are often primary particles of one mineral, which may not be very active as INP. Comparison of all measurements shows that immersion and contact freezing are similarly efficient modes of ice nucleation with ATD. Contact freezing experiments performed at a 2 s residence time yielded higher freezing efficiencies than at 4 s, which is compatible with adhesion freezing or immersion freezing but not with a collisional freezing mechanism. If particles became immediately immersed after contacting the droplet, freezing would occur in immersion mode also when a contact freezing experiment is performed. Indeed, the surfaces of many mineral dusts like quartz and feldspars are covered with hydroxyl groups, which render surfaces hydrophilic (Koretsky et al., 1997). Shang et al. (2010) measured contact angles of water droplets on clay films and found, for illites, a dependence of contact angles on relative humidity and on the exchangeable cations: the contact angle of Ca-illite sank from 28.3 to 21.6° when RH was raised from 19 to 100 %. At 33 % RH, contact angles ranged between 23.3 and 34.2° for illites saturated with different cations (Na, K, Mg or Ca). Contact angles of $31\text{--}35^\circ$ were measured for quartz (Szyzka, 2012). When we sprinkled ATD on a water surface, most particles were immediately immersed and sank to the bottom. This suggests that when ATD particles collide with water droplets, the particles become immediately immersed such that in immersion freezing and contact freezing experiments the immersion mode is probed.

5.2.3 Kaolinite

X-ray powder diffraction showed that Fluka kaolinite (K-SA), which is used in this study, contains only 82.7 % kaolinite but 5.4 % illite/muscovite, 5.9 % quartz and 4.5 % K-feldspar (Atkinson et al., 2013). The clay minerals illite/muscovite and kaolinite tend to form small crystals and are presumably enriched in the particle fraction with diameters < 500 nm, while quartz and K-feldspars may be overrepresented in the fraction with diameters > 500 nm. K-feldspars and illite are known to be efficient ice nuclei (Atkinson et al., 2013; Hiranuma et al., 2015) and may dominate freezing when many particles are present in a sample (Pinti et al., 2012). When only one particle is present, this is likely to be a kaolinite particle. Kaolinite is a clay mineral with the formula $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$. It has a layered structure with octahedral aluminum and tetrahedral silicon layers. It forms plate-like crystals with sizes of several hundred nanometers to micrometers and typical thicknesses of 30–50 nm (Hu and Michaelides, 2007, 2008). These plates have a hydrophilic octahedral Al–OH surface and a rather hydrophobic tetrahedral siloxane (Si–O) surface. The edges of the plates are terminated by oxygen atoms or hydroxyl groups and are hydrophilic. Šolc et al. (2011) computed a contact angle of 105° for nanodroplets on the tetrahedral siloxane surface by force-field molecular dynamics. Nanodroplets spread on the octahedral surface indicating a contact angle of 0° . Shang et al. (2010) measured a contact angle of about 18° for water droplets on kaolinite films. This experimental value represents an averaged value over all kaolinite surfaces. The energetically most favorable configuration is therefore when the kaolinite particle adheres to the water surface with the siloxane surface exposed to air. Whether a kaolinite particle realizes this configuration may depend on the orientation of the particle when it contacts the water droplet. When we sprinkled kaolinite powder on water, we observed that some particles floated on the surface for hours, while others became totally immersed and sank to the bottom within seconds. The lower freezing efficiency observed for a 2 s residence time in the CLINCH chamber compared with 4 s is incompatible with a collisional freezing process but in accordance with adhesion freezing or immersion freezing. A particle on the surface can induce ice nucleation in the immersion mode with the part immersed in water or in contact mode with the part exposed to air. While it is likely that a kaolinite particle that hits a water droplet adheres to the surface and exposes the hydrophobic siloxane surface to air, it is less clear whether particles that underwent droplet activation stick to the surface or whether they are totally immersed in the growing droplet. The conditions during activation, such as supersaturation or growth rate of the droplet, may also dictate which is the case. The immersion and contact freezing studies compiled in Fig. 6 suggest that adhesion freezing is more efficient than immersion freezing with an onset temperature that is about 3 K higher. Ladino et al. (2011), who

compared their contact freezing data from CLINCH with immersion freezing measurements from Lüönd et al. (2010) using IMCA–ZINC, concluded that there are some indications of contact freezing to be more efficient than immersion freezing. Pitter and Pruppacher (1973) compared contact and immersion mode freezing temperatures in wind tunnel experiments by exposing water droplets to kaolinite particles that were injected into the air stream. They estimated that a droplet captured several thousands of particles, which explains the much higher median freezing temperature of 261 K compared with this study. In accordance with our experiments, they found a clear shift to lower freezing temperatures when changing from contact to immersion mode experiments. Hoffmann et al. (2013b) found that contact freezing dominates over immersion freezing for droplets levitated in an electrodynamic balance that were exposed to a flow of particles of kaolinite KGa-1b. Svensson et al. (2009) investigated contact freezing using an electrodynamic balance to levitate droplets exposed to a flow of Fluka kaolinite particles. They observed contact freezing below 249 K for dry conditions and a freezing threshold of 267 K when the air was humidified. This value is higher than the one reported for the freezing of bulk suspensions of Fluka kaolinite (K-SA) by Pinti et al. (2012).

It is not clear which surface of kaolinite is responsible for ice nucleation. Using grand canonical Monte Carlo simulations, Croteau et al. (2008, 2010) showed that the Si–O surface remained dry up to water vapor saturation, while the edges and the Al–OH surface are much more hydrophilic and adsorb up to a monolayer of water at water saturation. Adsorbed water on the octahedral Al–OH surface exhibits hexagonal patterns but no close lattice match with ice (Croteau et al., 2008, 2010). Simulations by Zielke et al. (2016) showed that for the Al surface, reorientation of the surface hydroxyl groups is essential for ice nucleation. On the siloxane surface, ice nucleates via an ordered arrangement of hexagonal and cubic ice layers, joined at their basal planes, where the interfacial energy cost is low. Experimentally, much higher adsorption was determined, showing that most adsorption probably occurs on surface irregularities such as adsorbed ions or surface defects like trenches, pits and steps (Schuttlefield et al., 2007; Tabrizy et al., 2011). Croteau et al. (2010) have shown that adsorption is much higher on trenches than on the defect-free surface. Ice nucleation may therefore occur on liquid patches on an otherwise dry surface (Conrad et al., 2005). The wetting state of a nucleus may therefore be a crucial parameter for ice nucleation by kaolinite. This would be in accordance with the higher nucleation temperatures observed by Svensson et al. (2009) in humid conditions and point to an adhesion freezing mechanism.

6 Summary and conclusions

This study confirms the findings of Nagare et al. (2015) that theoretical formulations give too low collision efficiencies at subzero temperature for particles in the accumulation mode. In CLINCH, droplets evaporate, giving rise to diffusiophoresis and thermophoresis. Moreover, droplets and particles are charged. Freezing efficiencies calculated from theoretical formulations of collision efficiencies are more than 1 order of magnitude higher than the highest possible value of $FE = 1$. An assessment of the relevance of contact compared to immersion freezing is therefore limited by knowledge of collision efficiencies. To improve calculated collision efficiencies, formulations of thermophoresis and diffusiophoresis should be reassessed.

Comparing contact freezing efficiencies acquired at 2 s ($FE(2\text{ s})$) and 4 s ($FE(4\text{ s})$) residence times enables conclusions regarding the freezing mechanism. For contact freezing experiments with AgI, freezing efficiencies at 2 s and 4 s residence times were the same within error when the droplets collected on average only one particle during their time in the chamber. This is in accordance with a collisional contact freezing mechanism. However, adhesion freezing and immersion freezing cannot be excluded if these processes occur at a high rate. For experiments with ATD and kaolinite $FE(2\text{ s})$ was smaller than $FE(4\text{ s})$, which is incompatible with immediate freezing after contact. Therefore, immersion freezing or adhesion freezing must be at work for these INPs. The comparison of contact and immersion freezing experiments did not confirm a general enhancement of freezing efficiency in contact mode relative to immersion mode. One reason for this may be that in CLINCH and IMCA–ZINC experiments, the particles are free to realize the energetically most favorable position in or on the droplet. For AgI particles the freezing efficiency in CLINCH experiments was less than in IMCA–ZINC and the onset temperature was shifted to lower values. This is further investigated in Mar-

colli et al. (2016). For ATD, freezing efficiencies in contact and immersion mode were similar. For kaolinite particles, contact freezing became detectable at a higher temperature than immersion freezing. A specific dependence on the INP for the enhancement of contact freezing relative to immersion freezing is in accordance with Gurganus et al. (2014), who observed an increased efficiency for nucleation at the three-phase contact line in the case of nanoscale but not for microscale textures. In most experiments of contact freezing inside out, the position of the particle with respect to the droplet is fixed by the design of the experiment (Shaw et al., 2005; Fornea et al., 2009; Gurganus et al., 2014). Whether a particle adheres to the surface or becomes totally immersed in a droplet depends on the wetting of the particle with water. A contact angle of 0 corresponds with complete wetting; for higher values, the wetting is only partial. Our observations of particles that were gently sprinkled on water confirmed the predictions based on contact angles. Our experiments and calculation suggest that AgI particles partition to the droplet surface for contact and immersion freezing experiments. ATD particles seem to have highly hydrophilic surfaces that lead to fast immersion of the particles so that there is no time for adhesion freezing and immersion freezing prevails. Kaolinite forms plate-like crystals with a hydrophobic siloxane surface; all other surfaces are hydrophilic. It is therefore energetically most favorable when the hydrophobic surface of kaolinite particles is exposed to air. For this configuration, adhesion freezing and immersion freezing can compete.

7 Data availability

To get access to the data please contact Claudia Marcolli (claudia.marcolli@env.ethz.ch).

Appendix A: Wetting of particles

The wetting behavior of particles can be quantified by the contact angle α , which is related to the surface tensions of water with air (σ_{LA}) and of solids with air (σ_{SA}) and the interfacial tension between solids and water (σ_{SL}) through the Young equation (Hołownia et al., 2008) as follows:

$$\cos \alpha = \frac{\sigma_{SA} - \sigma_{SL}}{\sigma_{LA}}. \quad (\text{A1})$$

The change in surface tension when the particle that adheres to a surface of the droplet becomes totally immersed in the droplet is given as (Hołownia et al., 2008)

$$\Delta\sigma = \sigma_{SL} - \sigma_{SA} + \sigma_{LA} \quad (\text{A2})$$

Using Young's equation the change of surface tension is

$$\Delta\sigma = \sigma_{LA}(1 - \cos \alpha). \quad (\text{A3})$$

The change in the interfacial energy is given by

$$\Delta G = \Delta\sigma A, \quad (\text{A4})$$

where A is the surface area of the particle exposed to air when the particle adheres to the surface of the droplet. Considering a cubic particle and neglecting the curvature of the droplet, the area to be immersed in the droplet would be the area of one face of the cube. The particle will immerse in the droplet for negative ΔG and will remain on the surface for positive ΔG . As can be seen from Eq. (A4), ΔG is always positive and becomes zero for $\alpha = 0^\circ$. This means that in the absence of other forces, complete wetting of the particle surface by water is needed for total immersion of the particle in the droplet.

Table A1. List of symbols.

A	Surface area of the particle (m^2)	C	Concentration of particle (m^{-3})
CE	Collision efficiency	FE	Freezing efficiency
FF	Frozen fraction of droplets	L	Effective length experienced by the droplet (m)
l	Length of chamber (m)	N	Number of collision between droplet and INP
R	Radius of the droplet (m)	r	Radius of the particle (m)
$U(R)$	Terminal velocity of droplet (ms^{-1})	V_{flow}	Flow velocity in the chamber (ms^{-1})
α	Contact angle	σ_{SA}	Surface tension between particle and air (Jm^{-2})
σ_{LA}	Surface tensions between air and liquid (Jm^{-2})	σ_{SL}	Interfacial tension between particle and water (Jm^{-2})

Author contributions. B. Nagare carried out the CLINCH experiments and evaluations. A. Welti carried out IMCA–ZINC experiments. B. Nagare and C. Marcolli prepared the manuscript. O. Stetzer supervised the laboratory work, and U. Lohmann supervised the work overall.

Acknowledgements. This work was supported by the Swiss National Foundation, project 200020_150169. B. Nagare acknowledges the financial support by ETH Zurich. We thank Zamin Kanji, Ulrich Krieger, Jan Henneberger and Joel Corbin for useful discussions.
